[57] **ABSTRACT**

A system is provided for eliminating time-consuming, unnecessary transfers of data over networks such as the the World Wide Web while at the same time guaranteeing timeliness of the data used by recipients. Timeliness is assured by immediately sending small data-notification messages whenever data becomes relevant or changes. Efficiency is guaranteed by transmitting the data itself only when requested by the recipient of a data-notification message. In particular, recipients are alerted to the presence of, and changes in, data they might use by data-notification messages containing a timestamp, the data location, and a checksum. Based on the timestamp, the recipient can determine whether the data-notification message contains timely information or should be ignored. Based on the data location and checksum, the recipient can determine whether it already has the current version of the data in question, for example stored in a cache.

**SYSTEM FOR SENDING SMALL POSITIVE
DATA NOTIFICATION MESSAGES OVER A
NETWORK TO INDICATE THAT A
RECIPIENT NODE SHOULD OBTAIN A
PARTICULAR VERSION OF A PARTICULAR
DATA ITEM**

FIELD OF THE INVENTION

This invention relates to the efficient and timely communication and update of data stored in a repository such as one or more World Wide Web servers to a number of nodes using that data in a computer network, and more particularly to the use of checksums and timestamps to indicate version changes for the data.

BACKGROUND OF THE INVENTION

In networked applications involving many users widely dispersed on the Internet working with a collection of many large evolving data files, the problem arises as to how the existence and contents of these files are communicated to the various users. When data is stored in the World Wide Web, the location of each data file is named by a Uniform Resource Locator, or URL. Users find out about the existence of data files via URLs stored in other files or otherwise communicated to them. Users interact with the data using a 'web browser', which can fetch the data corresponding a URL.

The most straightforward way to ensure that a user will always have timely up-to-date information about the contents of a given data file is for a web browser to fetch the contents of the file from its source whenever a user wishes to inspect or otherwise use the data referred to by a URL. However, this approach is quite unsatisfactory for several reasons. First, since these data files usually change relatively slowly, the same identical file contents are typically fetched many times if a user uses the same URL many times. This wastes network bandwidth. Second, since each fetch takes a considerable amount of time, i.e., has high latency, a user has to wait for a considerable amount of time every time he wishes to use a URL. This wastes the user's time.

To attempt to overcome these problems, typical web browsers store local copies of data files they have retrieved via URLs. This approach, which is referred to as 'caching', means that while it is costly to retrieve a file the first time it is used, the data can be obtained with no network usage and very little time delay for subsequent use.

Caching is essential, because it leads to a dramatic improvement in network efficiency and URL access speed. However, it does not ensure that a user has up-to-date information about the contents of a given URL. Quite the contrary, as soon as the data file referred to by a URL changes, cached copies of the file become obsolete, and any user using a cached copy is using incorrect data.

To counteract this problem with caching, typical web browsers retrieve not only the data corresponding to a URL, but also a time-to-live record indicating how long the data is expected to be valid. Once this time has expired, the data is removed from the cache so that it will be re-retrieved the next time the user consults the URL.

This time-to-live approach is better than caching with no time limit. However, it still does not ensure that a user has up-to-date information about the contents of a given URL. The problem is that, for all but a very few URLs, it is not possible to predict in advance when the next change in the data will occur. If the predicted time-to-live is too short, then

2

the data will be wastefully re-retrieved even though it has not changed. If the predicted time-to-live is too long, then the user will end up using obsolete data.

Because caching, with or without time-to-live indications, does not guarantee up-to-date data, users are forced to explicitly request the re-retrieval of data whenever they want to be sure that they have up-to-date information. This is inefficient because most of the time, the data that is re-retrieved has not changed and is therefore unnecessarily transmitted. This also wastes the user's time, because he has to wait until the entire data file has been re-retrieved before he can know whether it has changed. This is also awkward, because the boundaries between sources of data are often not made apparent to the user, and therefore it can be difficult for a user to know when explicit requests for re-retrieval have to be made.

What is needed is an automatic way of detecting when the data corresponding to a URL changes and therefore must be re-retrieved, and doing the re-retrieval when and only when it is necessary.

The basic situation above involves a single user interacting with various sources of data. The problem of ensuring timely up-to-date access to changeable data is even more complex when many users are simultaneously interacting with each other and with various sources of data. The problem is greater because the heavy network demands of multi-user interaction mean that avoiding the waste and delay of unnecessary re-retrievals of data is even more important than in a single-user situation. In addition, further complications arise because it is important that when a data file changes, all the interacting users see this change at the same time.

For example, consider applications involving networked multi-user virtual environments. In these applications users interact in a three dimensional world generated by computer graphics and digital sound generation. For this to work, each user must be provided with the description of the virtual world they are in, the world being a composite of data files independently designed and controlled and brought together for the purposes of the interactive simulation. Up-to-date information about all these files must be efficiently communicated to each user in a timely fashion.

The best developed current example of a networked multi-user virtual environment is the military training system that is based on the IEEE Distributed Interactive Simulation protocol, DIS. This environment supports virtual war games in which users in simulated tanks, trucks, aircraft and other military vehicles interact in a virtual landscape.

The description of the virtual world in a networked multi-user virtual environment can be divided into two broad categories: small rapidly changing pieces of information such as the position of a particular tank or airplane, and large slowly changing data such as the appearance of parts of the landscape and individual vehicles.

The focus of the DIS protocol is the efficient low latency communication of small rapidly changing data. It sidesteps the problem of timely up-to-date communication of large slowly changing data by requiring that this data must all be communicated before a simulation begins and cannot change during a simulation. Specifically data sets representing the appearance of the vehicles, the shape of the terrain, and other artifacts are pre-stored at each network node, and linked directly into the simulation programs. Updates can only be introduced through a cumbersome process of notification to each of the users, oftentimes involving electronic mail to specify that new data is available and instructions for downloading and installation.

In order to support a wider variety of applications, such as iron-stop networked virtual environments in which users can generate their own spaces, it is essential to support the communication and update of large slowly changing simulation data while a simulation is in progress. This must be done very efficiently because network communication is at a premium in such a simulation. In addition, it must be done without user intervention, because it is desired that users concentrate wholly on the simulation itself, not on the underlying communication mechanisms.

Again, what is needed is an automatic way of detecting when remotely controlled data changes and therefore must be reloaded, and doing the reloading when and only when it is necessary.

SUMMARY OF INVENTION

A fundamental conflict underlies the problem of ensuring access to remote data that is timely and up-to-date as well as efficient and low-latency. To ensure timely up-to-date access to remote data, there has to be frequent communication of information about what versions of what data are available. However, to ensure efficient low-latency access to remote data, the data has to be cached locally and there must be very infrequent communication of the data itself.

The subject invention solves this problem by separating the communication of information about the state of data from the communication of the data itself. In particular, the subject system uses the frequent communication of small data-notification messages to ensure that data is timely and up-to-date while minimizing the number of times the data itself has to be communicated.

The key components of a data-notification message are a data location and a checksum on the data. The data location specifies where the data can be found. For example, when operating over the World Wide Web, the data location is specified using a URL. The checksum acts as a compact fingerprint indicating the version of the data, by summarizing the contents of the file.

It will be appreciated that the standard way of referring to versions of a data file is via a version number that is incremented each time the file is changed. However, the problem with version numbers is that their relationship to a data file is entirely arbitrary. Unless the version number is explicitly stored in the file, there is no way to look at a copy of the file in isolation and determine what version the copy corresponds to. Unfortunately, most standard data formats do not contain version numbers. Further, those that do contain the version numbers store these numbers in different places and use incompatible version numbering schemes. In addition, it is typically all too easy to change the data in a file while forgetting to change the version number. Thus, in summary, version numbers are not uniformly available, cumbersome to deal with, and not totally reliable as an indicator of whether a data file has changed.

In contrast to version numbers, whose association with a file is arbitrary, a checksum is computed from the data in a file. This gives checksums three key advantages. First, they can be applied to any kind of file without making any changes in or assumptions about standard formats. Second, they can be uniformly applied to all files. Third, they are almost completely reliable. Since they are computed from the file, it is impossible for someone to change a file while forgetting to change the checksum.

A variety of different checksum algorithms are available; however, they all have the property that they summarize the file as a whole using a small number of bits and with high probability, any change in the data will force a change in the checksum.

An easy to understand and easy to compute checksum algorithm is to divide the data into a series of 32-bit chunks and then add all the chunks together ignoring overflow to produce a 32-bit summary of the data as a whole. Changing any bit in the data will almost certainly change the checksum. However, there are many kinds of simultaneous changes to the data what will leave the checksum unchanged. For instance, adding 1 to one part of the data while subtracting 1 from another.

To avoid this kind of problem, more complex but much higher quality checksum algorithms have been developed such as cyclic redundancy checks, see D. V. Sarwate "Computation of cyclic redundancy checks via table look-up", Communications of the ACM, 31(8), pp. 1008-1013, 1988. Using these high quality algorithms, one can compute a 32-bit checksum that will change with extremely high probability no matter how the data is changed. In particular, using these algorithms, the probability that a typical change to the data will force the checksum to change approaches the theoretical limit of $1-2^{-32}=0.9999999998$.

If greater reliability than this is required one can use a longer checksum. Alternatively, in the extremely unlikely event that a new version of the data has the same checksum as an earlier version, one can arrange for the new version to have a different checksum by making an insignificant change to the underlying data, such as adding a blank line at the end of a text file. Almost every type of file can readily tolerate some sort of insignificant perturbation.

A final advantage of checksums is that in addition to allowing the version of a copy of a data file to be unambiguously identified, checksums can be used to verify that a data file has been correctly transmitted. The reason for this is that any errors in transmission will also change the checksum.

In summary, a data-notification message including a data location and 32-bit checksum can describe a specific version of a data file with almost total certainty in a very small space. There are several ways that data-notification messages can be used to ensure access to remote data that is timely and up-to-date as well as efficient and low-latency.

For example, data-notification messages could be used to improve the performance of web browsers as follows. This being a web-based application, URLs would be used to specify data locations. A browser would cache data files when retrieved, but instead of storing them with a time-to-live indicator would store them with their checksums. Whenever the user wishes to inspect or otherwise use the data referred to by a URL, the browser would send a data-notification message to the source of the data in question including the checksum of the cached data and requesting that new data be sent if and only if the cached data is out of date. This approach allows the accuracy of the cached data to be checked frequently while ensuring that the data itself is transmitted only when the data has changed and the user wants to use it. The ability to cache World Wide Web data during and across sessions with notification when the data changes, avoids the presentation of stale data while retaining good performance.

Using data-notification messages with checksums in a web browser would permit a simple, rapid indication of versions, while at the same time providing a simplified verification procedure to ascertain the validity of the data, as well as the fact of a version change. It will be appreciated that checksums can be utilized with data regardless of format or file type, because the checksum can be computed from the data, and need not be stored with it.

One aspect of the subject invention is that, while the system is described here in connection with networks, the version change detection system is equally applicable to situations in which some or all of the data is transmitted by other means, the method of transmission being immaterial. For instance, the data cache in a web browser or other system could be preloaded with data from a CD-ROM or magnetic media rather than over a network, which could greatly reduce system initialization time. After this preload, data-notification messages could be used over the network without prejudice to the way the data was initially loaded.

As a second example, consider the case of supporting the efficient communication of large slowly changing data in a networked multi-user virtual environment. The subject invention was developed in the course of designing a scalable platform for networked multi-user virtual environments, called Spline. As an illustration, the following describes the way the subject invention operates in Spline.

To start with, it must be realized that the situation is somewhat different in Spline than in the web browser example in several ways. First, in the web browser example, there is an enormous amount of data the user might choose to use at any given moment and therefore only the user can tell what he will want next. Therefore it is appropriate that the data-notification messages flow from the user to the sources of data. In contrast, in a multi-user virtual environment, it can be reliably predicted what large slowly changing data a given user needs access to based on where the user is in the virtual world. For instance, he needs to access the description of the landscape immediately surrounding him and the descriptions of the various objects near him. As a result, since the user's need for data can be externally predicted, it is appropriate for data-notification messages in Spline to flow from the sources of data to the user, rather than vice versa. The key advantage of this is that users can be informed of changes in data files the instant they happen. Further, users can be informed of the need for data somewhat in advance of the moment when it becomes essential, thereby allowing time for the data to be retrieved over the network if necessary.

Second, the network communication situation is more demanding in a networked multi-user virtual environment than when using a web browser. In particular, the messages containing small rapidly changing data, e.g., positions of objects, must be communicated with very low latency. The only practical way to achieve this low latency when communicating between large numbers of users is to utilize multicast messages using the User Datagram Protocol, UDP. An unfortunate aspect of this is that UDP messages are not guaranteed to arrive in order. As a result, some mechanism must be provided for ensuring that late arriving messages will not cause problems.

Specifically, suppose that a message M_1 is sent. Suppose also that at some later time a message M_2 containing new data that renders M_1 obsolete is sent. It is unfortunately the case that using UDP, a given user U might receive M_1 after M_2 . Unless something is done to prevent it, this will cause U to end up with the obsolete data in M_1 , rather than the up-to-date data in M_2 .

This problem is dealt with in Spline by including a timestamp in every message and associating a timestamp with each piece of data stored by a user. Using these timestamps, it is easy to ignore data that arrives too late to be useful. Specifically in the example above, U would ignore message M_1 when it arrives because it contains a timestamp that is less than the timestamp on the corresponding stored data, this stored timestamp having come from M_2 .

In Spline, the subject invention is embodied by transmitting UDP data-notification messages containing URLs with a timestamp added to each message so that data-notification messages that have arrived out of order and are no longer timely can easily be ignored. These data-notification messages are sent out by the sources of data whenever a new data file becomes available and whenever a data file changes.

An underlying assumption of this particular embodiment is that at any point in time, there is a single point of control for each data set, and thus for each URL. This means that only one site may be sending out messages about a URL, which avoids problems that could otherwise arise with sites receiving inconsistent messages from competing sources of information about a given URL.

Most of the time, a Spline process operates based on cached versions of the large slowly changing files that are needed for generating computer graphics images and digital sound. This allows very efficient low latency operation. However, a Spline process continually monitors the data-notification messages it receives in order to verify that the cached data it is using corresponds to the latest versions available and to detect when new data is needed. This latter situation arises for example, when a new kind of object enters the virtual environment for the first time.

Whenever the need for new or changed data is detected, Spline fetches the new data over the World Wide Web using the URL in the data-notification message, verifies that the data was correctly received using the checksum, and caches the data, URL, and checksum for future reference. In contrast to DIS, this mechanism allows the timely communication at runtime of all data both small and large while ensuring that the cost of retrieving large data sets is only incurred when the data is new or changes.

Multicasting URLs provides efficient, scalable communication about large data sets. Note that the sender of a multicast message has no direct knowledge of how many recipients there will be, or how widely dispersed they may be, and so it is particularly advantageous to use a naming scheme like URLs which are a lingua franca across the entire internet. Note further, that the above system allows the large data sets themselves to be reliably communicated using standard World Wide Web protocols and software, while unreliable multicast protocols and channels are used for the data-notification messages referring to the URL data, with the probability of their receipt being improved by repeated retransmission at randomized intervals.

In summary, a system is provided for eliminating time-consuming, unnecessary transfers of data over networks such as the the World Wide Web while at the same time guaranteeing timeliness of the data used by recipients. Timeliness is assured by immediately sending small data-notification messages whenever data becomes relevant or changes. Efficiency is guaranteed by transmitting the data itself only when requested by the recipient of a data-notification message. In particular, recipients are alerted to the presence of, and changes in, data they might use by data-notification messages containing a timestamp, the data location, and a checksum. Based on the timestamp, the recipient can determine whether the data-notification message contains timely information or should be ignored. Based on the data location and checksum, the recipient can determine whether it already has the current version of the data in question, for example stored in a cache. The use of checksums makes it possible for the subject system to operate in conjunction with any kind of data without any

alteration of standard data formats and makes it possible for the recipient of data to independently verify that the data was correctly transmitted by computing the checksum. If, and only if, the recipient wishes to use the data and does not yet have the current version, the recipient requests transmittal of the current version. This guarantees that the data itself is sent only when absolutely necessary. In one embodiment, the data is transmitted over the World Wide Web and the data location is specified by a Uniform Resource Locator, URL.

In a further embodiment, the data-notification messages are transmitted via multicast to a large number of recipients, while allowing the large data sets themselves to be delivered through other, more suitable means.

BRIEF DESCRIPTION OF DRAWINGS

These and other features of the subject invention will be better understood taken in conjunction with the Detailed Description in conjunction with the Drawings, of which:

FIG. 1A is a block diagram of the subject system indicating the utilization of timestamps and checksums for the indication of a change in the data available from a network server;

FIG. 1B is a diagrammatic representation of a scenario in which new data is provided at a source, with the source transmitting messages concerning the change in data to a recipient;

FIG. 2 is diagram of the data included in a network message, including timestamp, URL, and checksum;

FIG. 3 is a diagram of the information stored by the recipient to enable determination of a data change affecting its cache;

FIG. 4 is a flowchart indicating the process for sending a message with a timestamp, URL and checksum whenever the source desires to send any message about the data in that URL, including the recomputation of a checksum in response to data modification for the corresponding URL;

FIG. 5 is a flowchart of the process initiating upon receipt of a message sent by the process of FIG. 4 in which timestamps and checksums are evaluated for changes, followed by the request for the new data from the source, if needed; and,

FIG. 6 is a flowchart describing the process following the receipt of new data in which a checksum is computed and compared with checksum in the cache entry to establish the validity of the new data.

DETAILED DESCRIPTION

Referring to FIG. 1A, a network 10 connects a source 12 and a recipient 14 at various nodes on the network. A web server 16 provided with data 18 is utilized to deliver data provided by the source to the recipient. It will be appreciated that while the system of FIG. 1A is described with the single recipient, the subject system can be utilized with multiple recipients.

FIG. 1A illustrates the situation where the data 18 provided to web server 16 has recently changed. It is important that when there is a change of data at source 12, recipient 14 be made aware of such change. The change in data is illustrated by the onscreen character 20, stored at the recipient, to be changed to the character 22 represented by data₂. In this case, the change involves the character represented being provided with a beard and glasses. In order to inform the recipient of the change, a checksum₂ and timestamp₂ are provided for the corresponding URL at 24 such that the message received at 26 contains the URL and the updated checksum and timestamp.

It will be appreciated that previously a message has been received by recipient 14 to indicate a particular URL and a prior checksum and timestamp. The information in this previous message, URL₁, checksum₁, and timestamp₁, is stored in data cache 30 along with the corresponding data data₁.

The information in the newly received message is compared at 28 with the cached information to determine whether a new version of the data must be retrieved. It will be appreciated that if there had been no previous version of the data in the cache, then a new version of the data would of course also have to be retrieved.

Each message sent from source 12 has a particular URL 32, a computed checksum 34, and a timestamp 36, with the computed checksum being a 32-bit quantity computed by a standard checksum algorithm. A variety of different checksum algorithms are available included easy to compute but low quality algorithms such as adding together successive chunks of 32-bits and more expensive but much higher quality algorithms such as cyclic redundancy checks see D. V. Sarwate "Computation of cyclic redundancy checks via table look-up", Communications of the ACM, 31(8), pp. 1008-1013, 1988.

Some applications may rely on the very high probability that any change to the data will result in a change in the checksum, while others may take active steps to ensure that all changes will result in new checksums. This can be accomplished in the extremely unlikely case that an updated data set has the same checksum as the previous version by making an insignificant change to the data, such as adding a space at the end of a text file, and verifying that this perturbation affects the checksum.

When a message is to be sent from source 12, the URL, checksum and timestamp are provided in the transmitted message at 38 as a packet of data transmitted over network 10. When source 12 makes a data change, the fact of the change is transmitted to the recipient 14, which upon comparing timestamps and checksums can determine if a change has occurred. If so, the new version is requested at 40 such that web server 16 provides the new data to the recipient.

Referring now to FIG. 1B, how this is accomplished is as follows. As can be seen, at steady state, and at time t₁, the source 12 is sending messages with the corresponding URL, checksum and timestamp to recipient 14. This information is cached at the recipient site.

At time t₂, a new version of the data is provided at the source, with a new checksum and timestamp being computed. At this time the recipient is unaware of the new data.

At time t₃, the source continues to send messages with the corresponding URL and the new checksum/timestamp. At the recipient, the message mentioning the new checksum and timestamp is received, and the new data is requested from the World Wide Web, with the local cache having its data marked as out of date. It will be noted that the old data may be utilized in the interim, before the new data is fetched from the Web Server.

At time t₄, the new data is received, and the recipient's cache is brought up to date.

What will be appreciated is that the recipients can be made aware in a very efficient manner of the generation of new data for a given URL. This notification is transmitted in a small packet, not necessitating the transmission of the new data until requested by the recipients. This eliminates the necessity of transmitting large packets of data each time there is a data change. The system also eliminates the necessity for the recipients to periodically check whether the

data they have stored has become obsolete. Further advantages of the subject system occur in a multicasting environment. For instance, since multicasting encourages the use of small packets, the subject system takes advantage of checksum/timestamp comparison system to provide notification of newly changed data to multicast users, at the same time allowing them to use more reliable means for obtaining the data itself. The subject system minimizes exposure to packet loss, because only small notification packets are sent via unreliable multicast network protocols. The sender may choose to issue redundant notification packets in order to improve the likelihood of their receipt.

More particularly, and referring now to FIG. 2, it will be appreciated that the network message 24 contains only the timestamp, URL, and the aforementioned checksum. This data format is sufficiently small so as to fit into a single UDP packet.

Referring now to FIG. 3, the data which is cached at the recipient is cached as illustrated by the fields 42, 44 and 46, with the timestamp/URL/checksum residing in field 42, and with field 44 indicating valid data. Field 46 caches the current data.

In operation, and referring now to FIG. 4, when source 14 is to send a message, the system determines at 50 whether data at the corresponding URL has been modified since the last message or is new. If so, the corresponding checksum is computed at 52. At 56, the URL and checksum are sent over the network with the corresponding timestamp generated at 54.

Referring now to FIG. 5, upon receipt of the message generated by the process of FIG. 4, as illustrated at 60, the timestamp is evaluated to ascertain if it is newer than the latest current message received, if any, concerning the corresponding data set. If so, and as illustrated at 62, the checksum is compared with that of the message, if any, which has been cached to ascertain whether the data has changed or is new. Upon the ascertaining of a change, and as illustrated at 64, the new checksum replaces the old checksum in the cache entry, the data in the cache entry is marked as being no longer valid, and a request for the new data is generated. Thereafter, as illustrated at 66, the new timestamp received is stored locally in the cache entry.

Referring now to FIG. 6, when the new data requested is received, its checksum is computed at 70 and is compared at 72 with the checksum in the cache entry. If it is the same as the checksum cached, then as illustrated at 74, new data is stored in the cache, with the DATA-VALID flag set to true. If there is a difference between the computed checksum and the checksum that has been cached, then an error signal is generated at 76 to effectuate an exit from this process.

Assuming that new valid data is cached, the process is completed as indicated by EXIT 78.

Subroutines for performing the indicated functions follow, with the code in ANSI C describing the operation of a scalable platform for interactive environments, called Spline.

at 54.

Referring now to Figure 5, upon receipt of the message generated by the process of Figure 4, as illustrated at 60, the timestamp is evaluated to ascertain if it is newer than the latest current message received, if any, concerning the corresponding data set. If so, and as illustrated at 62, the checksum is compared with that of the message, if any, which has been cached to ascertain whether the data has changed or is new. Upon the ascertaining of a change, and as illustrated at 64, the new checksum replaces the old checksum in the cache entry, the data in the cache entry is marked as being no longer valid, and a request for the new data is generated. Thereafter, as illustrated at 66, the new timestamp received is stored locally in the cache entry.

Referring now to Figure 6, when the new data requested is received, its checksum is computed at 70 and is compared at 72 with the checksum in the cache entry. If it is the same as the checksum cached, then as illustrated at 74, new data is stored in the cache, with the DATA-VALID flag set to true. If there is a difference between the computed checksum and the checksum that has been cached, then an error signal is generated at 76 to effectuate an exit from this process.

Assuming that new valid data is cached, the process is completed as indicated by EXIT 78.

Subroutines for performing the indicated functions follow, with the code in ANSI C describing the operation of a scalable platform for interactive environments, called Splinc.

/* Locale links */

/* A locale file is a list of entries of the following form:
   Things are in ascii at the moment to facilitate debugging.

1) a symbolic locale name beginning in column 1
   followed by information on lines starting with a SPACE.
A) The locale id (hex long), and the number of neighbors (int)
B) a line containing the boundary data (6 floats of box 2 floats radii)
C) groups of lines for each neighbor
   a) id of neighbor (hex long)
   b) transform (16 floats, column major order)
   c) reverse transform (16 floats, column major order)

Having above indicated a preferred embodiment of the present invention, it will occur to those skilled in the art that modifications and alternatives can be practiced within the spirit of the invention. It is accordingly intended to define the scope of the invention only as indicated in the following claims.

Having above indicated a preferred embodiment of the present invention, it will occur to those skilled in the art that modifications and alternatives can be practiced within the spirit of the invention. It is accordingly intended to define the scope of the invention only as indicated in the following claims. 5

What is claimed is:

1. A system for eliminating time consuming unnecessary transfers of data over a network, while at the same time guaranteeing timeliness of data used by a recipient node of said network, comprising: 10

a source of data coupled to said network,

means at said source for sending a command in the form of a small positive data-notification message over said network for each version of said data to indicate that a recipient node should obtain a particular version of a particular data item; 15

means at said recipient node and responsive to said small data-notification message for determining whether the data corresponding to said small data-notification message is already present; and, 20

means at said recipient node for fetching the data specified by said small data positive notification message if not already present at said recipient node, whereby said source commands via said small positive data-notification message that appropriate new data be fetched and available at said recipient node if not already there. 25

2. The system of claim 1, wherein said small data-notification message includes a checksum and data location. 30

3. The system of claim 2, and further including means at said recipient node and responsive to said checksum for ascertaining the validity of the corresponding data fetched over said network. 35

4. The system of claim 2, wherein said network is the World Wide Web and wherein said data location is a uniform resource locator URL.

5. The system of claim 2, wherein said determining means at said recipient node includes means at said recipient node for storing a previous small data-notification message and the corresponding data.

6. The system of claim 5, wherein said determining means at said recipient node further includes means for ascertaining whether for a received small data-notification message there exists a stored small data-notification message with the same data location and checksum, this being true indicating that the corresponding data is already available at said recipient node.

7. The system of claim 5, wherein said determining means at said recipient node further includes means for ascertaining whether for a received small data-notification message there exists a stored small data-notification message with the same data location and a different checksum, this being true indicating that the corresponding data has changed and needs to be refetched. 15

8. The system of claim 5, wherein said determining means at said recipient node further includes means for ascertaining whether for a received small data-notification message there exists a stored small data-notification message with the same data location, this being false indicating that the corresponding data is new and needs to be fetched. 25

9. The system of claim 5, wherein said small data-notification message includes a timestamp and wherein said determining means at said recipient node further includes means for ascertaining whether for a received small data-notification message there exists a stored small data-notification message with the same data location and a later timestamp, this being true indicating that said received small data-notification message is not timely and should be ignored. 35
